Abstract. A distance measure between objects is a key requirement for many data mining tasks like clustering, classification or outlier detection. However, for objects characterized by categorical attributes, defining meaningful distance measures is a challenging task since the values within such attributes have no inherent order, especially without additional domain knowledge. In this paper, we propose an unsupervised distance measure for objects with categorical attributes based on the idea, that categorical attribute values are similar if they appear with similar value distributions on correlated context attributes. Thus, the distance measure is automatically derived from the given data set. We compare our distance measure to existing categorical distance measures and evaluate on different data sets from the UCI machine-learning repository. The experiments show that our distance measure is recommendable, since it achieves similar or better results in a more robust way than previous approaches.

Keywords: categorical data, distance measure, heterogeneous data, unsupervised learning

1 Introduction

Distance calculation between objects is a key requirement for many data mining tasks like clustering, classification or outlier detection [16]. Objects are described by a set of attributes. For continuous attributes, the distance calculation is well understood and mostly the Minkowski distance is used [2]. For categorical attributes, defining meaningful distance measures is more challenging since the values within such attributes have no inherent order [4]. The absence of additional domain knowledge, further complicates this task.

However, several methods exist to address this issue. Some are based on simple approaches like checking for equality and inequality of categorical values, or create a new binary attribute for each categorical value [2]. An obvious drawback of these two approaches is that they can not reflect the degree of similarity or dissimilarity between two distinct values. Yet, more sophisticated methods incorporates statistical information about the data [8,9,10].

In this paper, we take the latter approach. In contrast to previous work, we take into account the quality of information that can be extracted from the data, in form of correlation between attributes. The resulting distance measure is called ConDist (Context based Categorical Distance Measure): We first propose a distance measure for each attribute separately. To this end, we take advantage of the fact that categorical attributes are often correlated, as shown in an empirical study [10], or by the fact that entire research fields exist which detect and eliminate such correlations, e.g. feature selection [7] or dimensionality reduction [13]. In order to calculate the distances for the values within a *tar*get attribute, we identify at first the correlated context attributes. The distance measure on target attributes is then based on the idea that attribute values are similar if they appear with similar value distributions on their corresponding set of correlated context attributes. Finally, we combine these distance measures on separate attributes to calculate the distance of objects, again taking into account correlation information. We argue that incorporating the correlation of context attributes and the target attribute itself are important in order to maximize the relevant distance information extracted from the data and mitigate the possibly incorrect influence of uncorrelated attributes.

Table 1 shows a sample data set. Let us assume, we want to calculate the distance between the different values of attribute *height*, i.e., *height* is our target attribute. As mentioned above, our distance measure calculates its distance based on the value distributions of other attributes. For the attributes weight and haircolor these distributions (P(X|H = small), P(X|H = medium)) and P(X|H = tall)) are shown in Figure 1. In the case of weight the distributions are different. Thus, they will add information to our distance calculations. However, the distributions for haircolor are the same for all values of the target attribute. Thus, they will not contribute information to our distance measure. At the same time, we can see that weight is correlated to height, since higher weight implies greater height with a high probability. For haircolor on the other hand, there is no correlation, since haircolor does not imply height. Since we also take this correlation information into account, we exclude uncorrelated attributes from the distance measure. Therefore, context attribute haircolor will not be taken into account when calculating distances between the values of height.

Overall, we propose an unsupervised distance measure for objects described by categorical attributes. Our new distance measure *ConDist* calculates distances by identifying and utilizing relevant statistical relationships from the given data set in form of correlations between attributes. With this approach, *ConDist* tries to compensate the lack of inherent orders within categorical attribute domains.

The rest of the paper is organized as follows: Related work on categorical distance measures is discussed in Section 2. Section 3 describes the proposed distance measure ConDist in detail. Section 4 gives an experimental evaluation and the results are discussed in Section 5. The last section summarizes the paper.

Table 1: Example data set which describes nine people with three categorical attributes. The attributes *height* and *weight* have natural orders. Whereas the attribute *haircolor* has no natural order. *Height* and *weight* are correlated to each other while the attribute *haircolor* is uncorrelated to the other two attributes. *ConDist* uses such correlations between attributes to extract relevant information for distance calculation.

#	height	weight	haircolor
1	small	low	blond
2	small	low	brown
3	small	middle	black
4	medium	low	black
5	medium	middle	brown
6	medium	high	blond
7	tall	middle	blond
8	tall	high	brown
9	tall	high	black

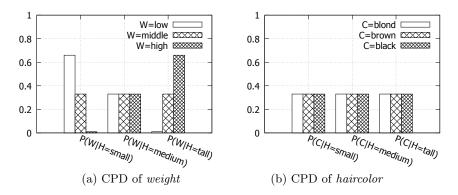

Fig. 1: This figure shows the conditional probability distributions (CPDs) of context attributes weight and haircolor, given the different values of the target attribute height based on Table 1. W stands for weight, C for haircolor and H for height. ConDist uses the difference between CPDs of context attributes to calculate the distance of target attribute values. Thus, weight can be used to calculate a meaningful distance between the values of height, while haircolor will yield the same distance for all three values of the target attribute.

2 Related Work

This section reviews related work on categorical distance measures. Distance measures can be divided into supervised and unsupervised. In the supervised setting, the class membership of the objects is provided and this information is exploited by the distance measures. In the unsupervised setting, assumptions and statistics about the data are exploited by the distance measures. Since the proposed distance measure is unsupervised, the following review considers only unsupervised categorical distance measures. We categorize them into distance calculation (I) without considering context attributes, (II) considering all context attributes, (III) considering a subset of context attributes and (IV) based on entire objects instead of individual attributes like the first three categories.

Boriah et al. [4] give a comprehensive overview of distances measures from the first category. In contrast to ConDist, these distance measures ignore available information that could be extracted from context attributes. For example, the distance measure Eskin [6] only uses the cardinality of the target attribute domain to calculate distances. [4] evaluated these distance measures for outlier detection and observed that no specific distance measure dominates all others.

The second category includes distance measures that employ all context attributes without distinguishing between correlated and uncorrelated context attributes. Li and Ho [10] compute the distance between two categorical values as the sum of dissimilarities between the context attributes' conditional probability distribution (CPD) when the target attribute takes these two values [10]. However, they do not recommend their distance measure for data sets with highly independent attributes. Similary, Ahmad and Dey [1] calculate the distance between two values using the co-occurrence probabilities of these two values and the values of the context attributes.

The third category selects a subset of context attributes for each target attribute. DILCA [8] is a representative of this category and uses Symmetric Uncertainty (SU) [18] for the selection of context attributes. SU is a measure which calculates the correlation between two attributes. In contrast to our work, all selected context attributes are weighted equally for the distance calculation.

The fourth category aims to compute distances between entire objects instead of distances between different values within an attribute. Consequently, the distance between different values within an attribute varies in dependence of the whole objects. Recently, Jia and Cheung [9] proposed such a categorical distance measure for cluster analysis. Their basic assumption is that two categorical values with high frequencies should have a higher distance than two categorical values with low frequencies. Therefore, they select and weigh a set of correlated context attributes for each target attribute using the normalized mutual information [3]. Jia and Cheung [9] compared their distance measure with the *Hamming Distance* on four data sets. They came to the conclusion that their distance measure performed better than the *Hamming Distance* on the evaluated data sets.

The proposed distance measure *ConDist* neither ignores context attributes (category I) nor simply includes all context attributes (category II). Instead, it follows the approach of the third category but extends the subset selection with a weighting scheme for context attributes. Furthermore, the target attribute itself is included in the distance computation. In contrast to the fourth category, two particular values within an attribute have always the same distance, independent of the objects enclosing that values. This allows *ConDist* to calculate a distance matrix for each attribute.

3 The Distance Measure ConDist

In this section, we introduce our distance measure *ConDist*. The core formula and the underlying ideas are proposed in the Section 3.1. Since *ConDist* first calculates the distance between single attributes before combining them, it requires adjusted distance functions for each attribute. In Section 3.2, we explain how these attribute distance functions are derived. Then, when combining the corresponding attribute-wise distances, *ConDist* uses a specific weighting scheme which is explained in Section 3.3. Both, the attribute distance functions as well as the weighting scheme use a set of correlated context attributes. Section 3.4 defines how the set of correlated context attributes is derived and how an impact factor is calculated which accounts for the varying amount of information dependent on different correlation values. Finally, we address the issue of how ConDist can be applied to objects characterized by continuous and categorical attributes in Section 3.5.

3.1 Definition of ConDist

This section provides the core formula of *ConDist*, calculating the distance between two objects characterized by attributes.

Let A and B be two objects in the data set D and let each object be characterized by n attributes. Furthermore, let the value of attribute X for object A be denoted by A_X . ConDist is a two-step process: First, it calculates the distance between each of the attributes of the objects A and B and then it combines them using attribute specific weights. Formally, *ConDist* defines the distance for two objects A and B as the weighted sum over all attribute distances:

$$ConDist(A,B) = \sum_{X=1}^{n} w_X \cdot d_X(A,B), \tag{1}$$

where w_X denotes the weighting factor assigned to attribute X (defined in Section 3.3) and $d_X(A, B)$ denotes the distance of the values A_X and B_X of attribute X in objects A and B (defined in Section 3.2).

The distance function d_X on the values of each attribute X needs to be calculated beforehand and is based on the idea that attribute values that appear with similar distributions of values in a set of correlated context attributes are similar. Whereas the weighting factor w_X accounts for differences in the number of context attributes and the degree of their correlation with the target attribute X. Both, the attribute distance functions d_X as well as the weighting factor w_X incorporate correlation information in order to maximize the relevant information that can be extracted from the data set and mitigate the possibly incorrect influence of uncorrelated attributes. For an example on differently correlated attributes and their influence on distribution based distance measures, please refer to Section 1 as well as Table 1 and Figure 1.

3.2 Attribute Distance d_X

As mentioned in Section 3.1, the distance d_X of values of a single attribute X is based on the idea that attribute values $x \in X$ are similar if they appear with similar distributions of values in a set of correlated context attributes. Thus, when comparing two objects A and B in attribute X, we first calculate the Euclidean distance between the two conditional probability distributions $P(Y|X = A_X)$ and $P(Y|X = B_X)$ for each attribute $Y \in context_X$ from the set of correlated context attributes $context_X$ of the target attribute X. Then, we weigh them based on an individual impact factor $impact_X(Y)$ (Section 3.4) and add up these distances for all attributes $Y \in context_X$. The impact factor accounts for the fact that the amount of information about the target attribute X in a context attribute Y decreases with both increasing and decreasing correlation cor(X|Y) as explained in Section 3.4. The resulting formula is:

$$\hat{d}_X(A,B) = \sum_{Y \in context_X} impact_X(Y) \sqrt{\sum_{y \in Y} \left(p(y|A_X) - p(y|B_X) \right)^2}, \quad (2)$$

where $p(y|A_X) = p(y|X = A_X)$ denotes the probability that value y of context attribute Y is observed under the condition that value A_X of attribute X is observed in the data set D.

As mentioned above, the attribute distance d_X relies on a set of correlated context attributes $context_X$ as defined in Section 3.4. Because every attribute is correlated to itself, the target attribute is also added to the set of context attributes. The motivation for including the target attribute is two-fold: First, it ensures that the list of context attributes is not empty even if all attributes are independent. Second, it ensures that the distance between two distinct values is always larger than 0. Thus, if no correlated context attributes can be identified, ConDist calculates the maximum distance for each distinct value-pair in target attribute X. In this case, the proposed distance measure ConDist reduces to the distance measure Overlap.

Note that, in the final definition of *ConDist* (Section 3.1), we normalize the attribute distance by the maximum distance value $d_{X,max}$ between any two values $x, u \in X$ of attribute X:

$$d_X(A,B) = \frac{\hat{d}_X(A,B)}{d_{X,max}} \tag{3}$$

3.3 Attribute Weighting Function w_X

ConDist compares objects based on the distances between each of the attribute values associated with the objects it compares (see Equation (2)). Each of these attributes is weighted differently by the weighting factor w_X . This section explains why these weights w_X are necessary and how they are calculated.

The weight w_X is especially necessary for data sets in which some attributes are independent from and others are dependent on each other: Consider the example from Table 1. For attribute *haircolor*, no correlated context attribute can be identified. Consequently, only the attribute *haircolor* itself is used for distance calculation and no additional information can be extracted from context attributes. Therefore, the normalized results of Equation (2) always results in the maximum distance 1 for any pair of non-identical values. In contrast, the attribute *weight* is a correlated context attribute for attribute *height*, and vica versa. Consequently, *ConDist* is able to calculate more meaningful distances for both attributes and these attributes should be weighted higher than *haircolor*.

However, average distances in attribute *haircolor* are larger than in attributes *weight* and *height*. Consequently, distinct values in attribute *haircolor* have implicitly larger relative weight than distinct values in attributes *height* and *weight*.

To solve this issue, the weighting factor w_X is introduced which assigns to each attribute X a weight based on (I) the amount of identified context attributes and (II) the impact of these context attributes on the target attribute X. This is formally defined in Equation (4).

$$w_X = 1 + \frac{\sum_{Y \in context_X} impact_X(Y)}{n \cdot c}, \tag{4}$$

where $context_X$ and $impact_X(Y)$ are defined as in section 3.4, n is the number of attributes in the data set D and c denotes a normalization factor defined as the the maximum of the impact function (see Section 3.4) which is independent of the attributes X and Y and amounts to $\frac{8}{27}$.

3.4 Correlation, Context and Impact

The attribute distance measures d_X (Section 3.2) and the weighting scheme w_X (Section 3.3) use the notion of correlation on categorical distance measures as well as a correlation related impact factor. Both are defined here.

Correlation cor(X|Y). A measure of correlation is required to determine an appropriate set of context attributes. For this purpose, we build a correlation measure on the basis of *Information Gain* (IG) which a widely used correlation measure in information theory [11]. The IG is calculated as described in the following formula:

$$IG(X|Y) = H(X) - H(X|Y),$$
(5)

where H(X) is the entropy of an attribute X, and H(X|Y) is the conditional entropy of attribute X given attribute Y.

According to this measure, the attribute X is more correlated with attribute Y than attribute W if IG(X|Y) > IG(X|W). The information gain IG(X|Y) is always less than or equal to the entropy H(X). Based on this observation, the function cor(X|Y) is defined as:

$$cor(X|Y) = \frac{IG(X|Y)}{H(X)}$$
(6)

and describes a correlation measure which is normalized to the interval [0, 1].

Context context_X. For both, the attribute distance d_X (Section 3.2) in ConDist as well as for the weighting scheme w_X (Section 3.3), the notion of a set of correlated context attributes $context_X$ is used. This set is defined using the previously defined correlation function cor(X|Y) and a user-defined threshold θ . That is, context attributes Y are included in $context_X$ only if their correlation with target attribute X is equal to or exceeds the threshold θ :

$$context_X = \{Y \mid cor(X|Y) \ge \theta\}$$
(7)

Impact $impact_X(Y)$. Again, for both, the attribute distance d_X (Section 3.2) as well as for the weighting scheme w_X (Section 3.3), a so called impact factor $impact_X(Y)$ is used. This factor accounts for the fact that the amount of information about the target attribute X in a context attribute Y decreases with both increasing and decreasing correlation cor(X|Y).

A high correlation value means that a value of a context attribute $Y \in context_X$ implies the value of a target attribute X with a high probability. For example, when we know that someone is heavy, it is more likely that this person is tall than small (see Table 1). Thus, in the extreme case of perfectly correlated attributes, the conditional probability distributions $P(Y|X = A_X)$ and $P(Y|X = B_X)$, for $A_X \neq B_X$ do not overlap. This means that using the Euclidean distance to calculate the similarity of those two CPDs (as in Formula (2)) limits the distance information gained from the context attribute to values of 0 (for $A_X = B_X$) and 1 (for $A_X \neq B_X$) after normalization in Formula (3).

A low correlation value means that a value of a context attribute $Y \in context_X$ implies little to no preference for a particular value of a target attribute X. This means that the similarity between the conditional probability distributions $P(Y|X = A_X)$ and $P(Y|X = B_X)$ may be random, thus, possibly conveying incorrect distance information.

However, since perfectly correlated attributes contribute at least no incorrect information, they are still used but weighted with smaller impact factors. In contrast, non-correlated attributes are excluded since they could contribute incorrect information.

Therefore, we choose a weighting function that (I) increases fast at the onset of correlation between attributes, (II) increases more slowly with existing, but partial correlation, and (III) decreases at nearly perfect correlation. In particular, we propose the impact function as depicted in Figure 2 and defined as:

$$impact_X(Y) = cor(X|Y) \left(1 - 0.5 \cdot cor(X|Y)\right)^2 \tag{8}$$

In general, any other function with similar properties can be chosen.

3.5 Heterogeneous Data Sets

Many real-world data sets contain both continuous and categorical attributes. To apply *ConDist* to such data sets, two situations have to be distinguished: either the target attribute is continuous or the context attribute is continuous.

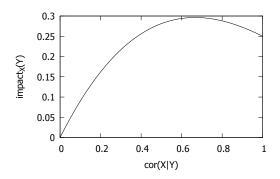

Fig. 2: Graph of the impact function $impact_X(Y)$ as defined in (8).

If the target attribute is continuous, no context attributes are necessary. The Minkowski distance can be used, but should be normalized to the interval [0, 1]. Since meaningful distances can be calculated for continuous attributes, the attribute weight w_X (see Section 3.3) should be maximized. If the context attribute is continuous, the continuous value range should be discretized. We propose to use the discretization algorithm TUBE [14], because it does not require any parameters. Other discretization algorithms can be used as well.

4 Experiments

This section presents an experimental evaluation of *ConDist* in the context of classification and clustering. We compared *ConDist* with *DILCA* [8], *JiaCheung* [9], *Quang* [10] and several distance measures presented in [4], namely *Eskin*, *Gambaryan*, *Occurrence Frequency (OF)* and *Overlap*.

4.1 Evaluation Methodology

Classification. A k-Nearest-Neighbour classifier is used to compare *ConDist* with existing categorical distance measures in the context of classification. For simplification, we fix k = 7 in all tests. We evaluate by 10-fold-cross validation and use the classification accuracy as evaluation measure. To reduce confounding effects of the generated subsets, the 10-fold cross-validation is repeated 100 times with different subsets for each data set. We finally compare the averages of the classification accuracies over all executions.

Clustering. The hierarchical WARD algorithm [17] is used to evaluate the performance of *ConDist* in the context of clustering. *ConDist* and its competitors are used to calculate the initial distance matrix as input for WARD. For simplification, the clustering process is terminated when the number of clusters is equal to the number of classes in the data sets. Performance is measured by *Normalized Mutual Information (NMI)* [15] which ranges from 0 for poor clustering to 1 for perfect clustering with respect to the predefined classes.

Table 2: Characteristics of the data sets. The column *Correlation* contains the average of the correlations between each pair of attributes in the data set, calculated by the function cor(X|Y), see Equation (6). The value ranges from 0 if no correlation exists to 1 if all attributes are fully correlated. The data sets are separated in three subsets from highly correlated to uncorrelated based on their average correlation.

Data Sets	Instances	Attributes	Classes	Correlation
Teaching Assistant Evaluation	151	5	3	0.336

Balance-Scale	625	4	3	0.000
Car	1728	6	4	0.000
Nursey	12960	8	5	0.000

Data Sets. For the evaluation of *ConDist* the *multivariate categorical data* sets for classification from the UCI machine learning repository [12] are chosen. We exclude data sets with less than 25 objects (e.g., *Balloons*) or which have mainly binary attributes (e.g., *Chess*). Furthermore, we include some *multivariate mixed data sets for classification* from the UCI machine learning repository [12] which mainly consist of categorical attributes and some numerical attributes with few discrete values: *Teaching Assistant Evaluation, Breast Cancer Winconsin, Dermatology* and *Post-Operative Patient*. Since not all competitors have an explicit way to process numerical attributes, we treated all numerical attributes as categorical. The final set of data sets is given in Table 2.

The data sets are divided in three subgroups: highly-correlated (Correlation ≥ 0.05), weakly-correlated (Correlation > 0) and uncorrelated (Correlation = 0).

4.2 Experiment 1 – Context Attribute Selection

Experiment 1 analyzes the effects when varying threshold θ (see Section 3.4) in *ConDist*'s context attribute selection. The threshold θ defines the minimum value of the function cor(X|Y) that a candidate attribute Y has to achieve in order to be selected as context attribute for the target attribute X. The higher

Table 3: Classification accuracies for various thresholds θ in *ConDist*. Each column contains the results in percent for particular thresholds θ .

		Threshold θ								
Data Set	0.00	0.01	0.02	0.03	0.05	0.10	0.20	0.50	1.00	
Soybean Large	91.74	91.74	91.79	91.80	91.82	89.75	89.36	89.63	91.30	
Lymphography	83.36	83.36	83.30	83.24	83.01	81.99	82.01	81.24	81.26	
Hayes-Roth	68.11	68.36	68.51	68.60	69.21	64.47	64.47	64.47	64.47	
TicTacToe	99.99	99.99	99.99	99.98	94.74	94.74	94.74	94.74	94.74	
Balance-Scale	77.35	78.66	78.66	78.66	78.66	78.66	78.66	78.66	78.66	
Car	88.98	90.56	90.56	90.56	90.56	90.56	90.56	90.56	90.56	
Average	84.92	85.45	85.47	85.47	84.67	83.36	83.30	83.22	83.50	

the threshold θ , the fewer context attributes are used. In the extreme case of $\theta = 0$, all context attributes are used for distance calculation. In the other extreme case $\theta = 1$, only the target attribute itself is used. For this experiment, a representative subset of two highly-correlated (*Soybean Large* and *Lymphogra-phy*), two weakly-correlated (*Hayes-Roth* and *TicTacToe*) and two uncorrelated (*Balance-Scale* and *Car*) data sets are used. The results can be seen in Table 3.

The average classification accuracy (I) increases with low thresholds θ , (II) reaches a peak at $\theta = 0.02$ and $\theta = 0.03$, (III) decreases slowly with medium high thresholds, (IV) reaches the minimum at $\theta = 0.5$ and (V) slowly increases with high thresholds again. For nearly all data sets, the classification accuracy stabilizes with increasing thresholds. The lower the attribute correlation within the data set, the faster this effect is reached. For uncorrelated data sets like *Car* and *Balance-Scale*, it can already be observed with thresholds greater than or equal to $\theta = 0.01$. Due to the peak for $\theta = 0.02$, this value is used for the further experiments in this paper.

4.3 Experiment 2 – Comparison in the Context of Classification

Experiment 2 compares *ConDist* with several categorical distance measures in the context of classification. All data sets from Table 2 are used. The results are given in Table 4, except for the data sets *Mushroom-Extended*, *Mushroom* and *Soybean Small*. These data sets are omitted in the table, since all distance measures reach 100 percent classification accuracy. Consequently, these data sets would only blur the differences between the categorical distance measures.

ConDist achieves the highest average classification accuracy of all distance measures. In the case of highly- and weakly-correlated data sets, context based categorical distance measures (ConDist, DILCA, JiaCheung and Quang) achieve mostly better results than other distance measures. In the case of uncorrelated data, previous context based categorical distance measures are inferior to ConDist and non-context based categorical distance measures.

Table 4: Comparison of categorical distance measures in the context of classification. Each column contains the classification accuracies in percent for a particular distance measure. The data sets are separated in three subsets from highly correlated to uncorrelated based on their average correlation.

Statistical Significance Test. In this test, we want to evaluate if the differences in Table 4 are statistically significant. Demšar [5] deals with the statistical comparison of classifiers over multiple data sets. They recommend the Wilcoxon-Test for the comparison of two classifiers. Based on their recommendation, we apply the Wilcoxon-Test with $\alpha = 0.05$ on the classification accuracies of Table 4. The results of this test are given in Table 5.

Table 5: Results of the Wilcoxon-Test comparing the classification accuracies of *ConDist* with each other distance measure. The first row contains the calculated p-value, the second rwo contains the result of the Wilcoxon-Test: *yes*, if *ConDist* performs statistically different, *no* otherwise.

	DILCA	Eskin	JiaCheung	Gambaryan	OF	Overlap	Quang
p-value	.0156	0.002	0.045	0.002	0.002	0.008	0.096
significant	yes	yes	yes	yes	yes	yes	no

Table 5 shows that there is a significant difference between *ConDist* and the distance measures *Eskin*, *JiaCheung*, *Gambaryan*, *OF* and *Overlap*. However, the test fails for *ConDist* and *Quang*.

Table 6: Comparison of categorical distance measures in the context of clustering. Each column contains the NMI of the clustering results found by the WARD algorithm where the initial distance matrix is calculated with the particular distance measure. The NMI assigns low values to poor clusterings and high values to good clusterings with respect to the predefined classes. The data sets are separated in three subsets from highly correlated to uncorrelated based on their average correlation.

4.4 Experiment 3 – Comparison in the Context of Clustering

Experiment 3 compares ConDist with several categorical distance measures in the context of clustering. All data sets from Table 4 are used. The results are given in Table 6.

For some data sets (*Teaching Assistang Evaluation, Lymphography, Breast Cancer, Hayes-Roth, Post-Operative Patient, TicTacToe, Monks, Balance-Scale, Nursey* and *Car*) the clustering fails to reconstruct the predefined classes. For the remaining data sets, no distance measure dominates the other distance measures. However, most distance measures perform poorly on single data sets, whereas *ConDist* achieves more stable results.

Statistical Significance Test. In analogy to Section 4.3, the Wilcoxon-Test ($\alpha = 0.05$) is applied on the results shown in Table 6.

Except for *Eskin* and *Quang*, the results of the Wilcoxon-Test (Table 7) show no statistically significant differences.

Table 7: Results of the Wilcoxon-Test comparing the NMI of *ConDist* with each other distance measure used in the WARD algorithm. The first row contains the calculated p-value, the second row contains the result of the Wilcoxon-Test: *yes*, if *ConDist* performs statistically different, *no* otherwise.

	DILCA	Eskin	JiaCheung	Gambaryan	OF	Overlap	Quang
p-Value	0.293	0.008	0.057	0.552	0.182	0.100	0.035
significant	no	yes	no	no	no	no	yes

5 Discussion

5.1 Experiment 1 – Context Attribute Selection

Table 3 shows that a small threshold of $\theta = 0.02$ is already sufficient to remove noise and simultaneously receive correlation information. If the threshold θ is too high, many useful context attributes are discarded. This is especially the case for weakly correlated data sets, e.g. *Hayes-Roth* and *TicTacToe*. For *Hayes-Roth*, the decrease of classification accuracy is observed for $\theta > 0.05$, and for *TicTacToe* the decrease of classification accuracy is already observed for $\theta > 0.02$.

In contrast to this, if the threshold θ is too low, independent context attributes are added which may contribute noise to the distance calculation. This is especially the case for uncorrelated data sets, e.g. for $\theta = 0$ in *Balance-Scale* and *Car.* In contrast, *ConDist's* impact function $impact_X(Y)$ accounts for this effect in highly-correlated data sets.

Therefore, we recommend $\theta = 0.02$ for *ConDist*, because the experiments show that this threshold achieves the best overall results. Furthermore, for correlated data sets, *ConDists'* impact function handles this issue automatically.

5.2 Experiment 2 – Comparison in the Context of Classification

For of highly correlated data sets, distance measures using context attributes outperform other distance measures. However, for those data sets no best distance measures can be identified among the context based distance measures.

For uncorrelated data sets, previous context-based distance measures (*DILCA*, *Quang* and *JiaCheung*) achieved inferior results in comparison to *ConDist* and non-context based distance measures. This is because, e.g. *DILCA* and *Quang* use only context attributes for the distance calculation which results in random distances if all context attributes are uncorrelated.

In contrast, *ConDist* achieved acceptable results because not only correlated context attributes, but also the target attributes are considered. This very effect is also illustrated by the comparison between *ConDist* and *Overlap*. *ConDist* is equal to *Overlap* if no correlated context attributes can be identified, see uncorrelated data sets (*Monks, Balance-Scale, Nursey* and *Car*) in Table 4. However, for weakly- and highly-correlated data sets, *ConDist's* advantage of considering context attributes achieves better results than *Overlap*. The improvement of *ConDist* can be statistically confirmed by the Wilcoxon-Test (see Table 5).

5.3 Experiment 3 – Comparison in the Context of Clustering

Table 6 shows that the majority of the different distance measures reach roughly similar outcomes for individual data sets. This is because the clustering algorithm and its ability to reconstruct the given classes have much higher impact on the results than the distance measure used to calculate the initial distance matrix. However, it can be seen that the performance of single distance measures strongly decreases for individual data sets. For example, *JiaCheung* which often achieves good results, performs very poorly in the *Mushroom* data set. Similar observations can be made for *OF*, *Eskin*, *Quang* and *DILCA*, mainly in the data sets *Breast Cancer Winconsin*, *Mushroom*, *Mushroom Extended*, *Dermatology* and *Audiology*. In contrast, *ConDist* is almost always among the best results and shows the most stable results for the different data sets.

Except for *Eskin* and *Quang*, the Wilcoxon-Test in Section 4.4 shows no statistical significant differences in the performance of *ConDist* and the compared distance measures. However, the results of Experiment 3 lead to the assumption that *ConDist* may be a more robust distance measure than its competitors.

6 Summary

Categorical distance calculation is a key requirement for many data mining tasks. In this paper, we proposed *ConDist*, an unsupervised categorical distance measure based on the correlation between the target attribute and context attributes. With this approach, we aim to compensate for the lack of inherent orders within categorical attribute by extracting statistical relationships from the data set. Such correlations are often present in real-world data sets [10].

Our experiments show that *ConDist* is a generally usable categorical distance measure. In the case of correlated data sets, *ConDist* is comparable to existing context based categorical distance measures and superior to non-context based categorical distance measures. In the case of weakly and uncorrelated data sets, *ConDist* is comparable to non-context based categorical distance measures and superior to context based categorical distance measures. The overall improvement of *ConDist* can be statistically confirmed in the context of classification. In the context of clustering, this improvement could not be statistically confirmed.

In the future, we want to extend the proposed distance measure so that it can automatically infer the parameter θ from the data sets. Additionally, we want to transform categorical attributes to continuous attributes with aid of the proposed distance measure.
